Abstract A pore-scale model is developed to simulate fluid-fluid interfacial area in variably saturated porous media, with a specific focus on incorporating the effects of solid-surface roughness. The model is designed to quantify total (film and meniscus) fluid-fluid interfacial area (A_{nw}) over the full range of wetting-phase fluid saturation (S_w) based on the inherent properties of the porous medium. The model employs a triangular pore space bundle-of-cylindrical-capillaries framework, modified with three surface roughness-related parameters. The first parameter (surface roughness factor) represents the overall magnitude of surface roughness, whereas the other two parameters (interface growth factor and critical adsorptive film thickness) reflect the microscale structure of surface roughness. A series of sensitivity analyses were conducted for the controlling variables, and the efficacy of the model was tested using air-water interfacial area data measured for three natural porous media. The model produced good simulations of the measured A_{nw} data over the full range of saturation. The results demonstrate that total interfacial areas for natural media are typically much larger than those for ideal media comprising smooth surfaces due to the substantial contribution of surface roughness to wetting-film interfacial area. The degree to which fluid-fluid interfacial area is influenced by roughness is a function of fluid-retention characteristics and the nature of the rough surfaces. The full impact of roughness may be masked to some degree due to the formation of thick wetting films, which is explicitly quantified by the model. Application of the model provides insight into the importance of the interplay between pore-scale distribution and configuration of wetting fluid and the surface properties of solids.

1. Introduction

The interface between immiscible fluids in porous media is a fundamental property for mass and energy transfer, contaminant retention, and biogeochemical reactions, which play a significant role in many disciplines including hydrology, environmental science, petroleum engineering, and soil mechanics (e.g., Costanza & Brusseau, 2000; Gvirtzman & Roberts, 1991; Hassanizadeh & Gray, 1993; Leverett, 1941; Pyrak-Nolte et al., 2008; Skopp, 1985). Fluid-fluid interfaces in porous media are typically considered to comprise two types: one consisting of films of wetting fluid associated with the solid surfaces (film-associated interface) and the other consisting of capillary-supported menisci residing in intergranular pore space (capillary or meniscus interface). The film-associated interfaces typically comprise a large fraction of total interfacial area at most wetting-phase saturations for natural porous media, often exceeding the capillary meniscus contributions by several orders of magnitude (Brusseau et al., 2006, 2007; Or & Tuller, 1999).

Surface roughness of natural grains is one of the most important properties affecting fluid-solid interactions in porous media. It encompasses different sources and types of features that span a wide range of spatial scales from nanometer to micrometer. The impacts of surface roughness on the displacement and distribution of fluids in porous media have been investigated for decades. For example, researchers have shown that surface roughness can affect fluid behavior by changing the degree of wettability (AlRatrout et al., 2018; Cassie & Baxter, 1944; Oliver et al., 1980; Wenzel, 1936). In addition, researchers have studied whether surface roughness has direct impacts on drainage and imbibition as measured with the soil water characteristic (SWC) curve (Dullien et al., 1989; Tokunaga et al., 2003). The relationship between grain surface roughness and hydraulic conductivity of porous media has also been investigated (Brown, 1987; Lampurlanés & Cantero-Martínez, 2006; Thompson & Brown, 1991; Tokunaga & Wan, 1997).

The influence of surface roughness on fluid-fluid interfaces in natural porous media has been discussed in prior experimental studies. For example, exponential increases in air-water interfacial area were measured at low water saturations with the gas-phase interfacial partitioning tracer test (IPTT) method (Costanza-Robinson & Brusseau, 2002; Kim et al., 1999; Peng & Brusseau, 2005). These measured interfacial areas are orders-of-magnitude greater than geometric-based solid surface areas calculated with the smooth-surface assumption. Conversely, they are consistent with specific solid surface areas measured using the N_2-BET method, which incorporates surface roughness. Interfacial areas measured with aqueous-phase IPTT methods have also been shown to be larger than geometric smooth-surface solid surface areas (Brusseau et al., 2007, 2008, 2015; Saripalli et al., 1997; Schaefer et al., 2000; Zhong et al., 2016). In addition, the total interfacial areas measured with both gas-phase and aqueous-phase IPTT methods are much larger than interfacial areas measured with X-ray computed microtomography, which has a resolution limit at the micrometer level (Brusseau et al., 2006, 2007, 2008, 2010; McDonald et al., 2016). These observations were attributed to the impact of surface roughness and its contribution to film-associated interfacial area. In contrast, interfacial areas measured with computed microtomography and IPTT methods were identical to each other and to the geometric smooth-surface solid surface area and the N_2-BET solid surface area for a glass-bead medium that has no measurable surface roughness (Lyu et al., 2017; Narter & Brusseau, 2010; Zhong et al., 2016).

Prior studies have developed several quantitative approaches for representing the influence of surface roughness on fluid-solid interactions. For example, the specific solid surface area (*SA*) has been used as a variable to implicitly incorporate surface roughness, and relationships between the maximum fluid-fluid interfacial area and *SA* have been developed (e.g., Brusseau et al., 2010; Or & Tuller, 1999; Peng & Brusseau, 2005). However, these efforts did not employ specific information about the surface-roughness structures. Conversely, other investigators have proposed quantitative descriptions of the structure of surface roughness. For example, Philip (1978) used such a description to examine the influence of roughness on film thickness for adsorbed and capillary condensed wetting fluid. Or and Tuller (2000) proposed a quantitative description of surface roughness, using a statistical distribution for the depth of pits to predict the hydraulic conductivity for film flow. They then generalized the model to the sample scale using a bundle-of-cylindrical-capillaries (BCC) network model in follow-up work (Tuller & Or, 2001). More recently, Zheng et al. (2015) simplified the quantification of roughness in a BCC-based model for producing SWC curves and predicting hydraulic conductivity. In their approach, the surface roughness was represented as the ratio between rough and smooth surface areas. These latter studies did not examine the relationship between surface roughness and fluid-fluid interfaces specifically. Hence, quantitative approaches still need to be developed to explicitly delineate the impact of surface roughness on fluid-fluid interfaces.

Over the past decades, a number of approaches have been used for the simulation of fluid-fluid interfaces in porous media, including (a) idealized pore-geometry models (e.g., Cary, 1994; Diamantopoulos & Durner, 2013; Likos & Jaafar, 2013; Oostrom et al., 2001; Or & Tuller, 1999); (b) thermodynamic-based models (e.g., Bradford & Leij, 1997; Grant & Gerhard, 2007; Leverett, 1941; Schroth et al., 2008); (c) pore-scale network models (e.g., Joekar-Niasar et al., 2010; Kawanishi et al., 1998; Kibbey & Chen, 2012; Reeves & Celia, 1996); (d) pore-morphology models (e.g., Chan & Govindaraju, 2011; Dalla et al., 2002); and (e) direct pore-scale numerical simulations using the Lattice Boltzmann Method (e.g., McClure et al., 2016; Porter et al., 2009, 2010). Models developed with the first two approaches can be expressed as analytical equations, while the other approaches require numerical treatments. Most prior studies have either focused only on meniscus-associated interfacial area—ignoring films—or included films but without considering the impact of solid surface roughness. In addition, performance testing of the models by comparison to measured interfacial-area data has to date been restricted to simple porous media such as glass beads or sands that have minimal to relatively small magnitudes of surface roughness, and to limited ranges of water saturations (>20%).

In the present study, a pore-geometry approach based on the triangular-pore BCC framework is used to develop a model to simulate total (film and meniscus) fluid-fluid interfacial area. The methodology incorporates and modifies the approach used by Zheng et al. (2015) to represent surface roughness, and extends it to specific quantification of fluid-fluid interfacial area. The influence of the controlling variables is illustrated via example simulations and a sensitivity analysis for model parameters. The efficacy of the model is

evaluated by application to air-water interfacial area data measured for three natural media. The simulation results are used to illustrate the influence of surface roughness on the magnitude of fluid-fluid interfacial area.

2. Model Development

2.1. Incorporating Surface Roughness

Traditional concepts of surface roughness are usually related to a surface elevation profile where each point on the surface has a vertical height relative to a reference plane. The arithmetic average (R_a) or root-mean-square (R_{rms}) of the relative heights at all points is often used to represent the surface roughness. However, researchers have raised concerns that this approach does not adequately represent the fractal geometry of rough surfaces (e.g., Ghanbarian et al., 2016), in which the actual surface structures may have a fractal growth that greatly exceeds the scale of traditional roughness. An alternative approach to define the effective roughness of a surface has been suggested as a "surface roughness factor," which defines the magnitude of "actual or effective" surface area vs. the geometric-base smooth surface area in one unit surface (e.g., Kamusewitz & Possart, 2003; Santamaría et al., 2012; Wenzel, 1936; Zheng et al., 2015). By definition, the geometric-base surface area is a low-resolution characteristic and is typically treated as smooth, whereas the actual surface area incorporates the effects of surface roughness across a range of higher-resolution scales. The term "rugosity" has also sometimes been used to emphasize its difference from traditional roughness (e.g., Beyhan et al., 2007; Liu et al., 2014).

A general approach to incorporate surface roughness for any given solid surface is used for this study, based on and revised from the methods employed by Zheng et al. (2015). By definition, the geometric base of a surface has a surface area defined as L_0 in its one-dimensional cross-section, which is termed the geometric smooth surface area (Figures 1a–1c). A rough surface is considered to have a surface area specified as L_r, representing the topological surface area. The surface roughness factor, X, is then defined as the actual surface area (L_r) divided by the corresponding geometric smooth surface area (L_0) for any unit of surface:

$$X = L_r/L_0. \tag{1a}$$

This factor can be considered as an index characterizing the degree to which the surface of a solid deviates from a functionally smooth surface. When wetting film is present on the same geometric base (Figures 1a–1c), its upper interfacial area (L_f), i.e., the fluid-fluid interfacial area, can be specified and compared to the same geometric base L_0. This produces an interfacial area factor, X_a, defined as follows:

$$X_a = L_f/L_0, \tag{1b}$$

where $1 \leq X_a \leq X$ at any saturation (Zheng et al., 2015). It is assumed that the system is homogeneous such that X is the same for all surfaces.

For rough surfaces, the involvement of capillary forces can in some cases retain additional wetting fluid beyond that of adsorption, producing thicker films (e.g., Israelachvili, 2011; Philip, 1978; Tokunaga, 2011). It is therefore assumed that under certain conditions the thicknesses of the wetting films will be sufficient to mask the full impact of roughness on interfacial area. The impact of roughness may be fully masked for some systems, particularly at higher wetting-phase saturations, which would result in smooth fluid-fluid interfaces (referred to as thick film as shown in Figure 1a). In this case, there is no roughness effect on interfacial area and $L_f = L_0$. At very low wetting-phase saturations where the matric potential is high, it is assumed that adsorptive forces dominate over capillary forces such that the film is only a few molecules thick (referred to as thin film as shown in Figure 1c) (e.g., Or & Tuller, 1999; Resureccion et al., 2011; Tokunaga, 2011). Under this condition, the interfacial area is equivalent to the actual solid surface area, i.e., $L_f = L_r = XL_0$. Under intermediate-saturation conditions, the combination of surface adsorption and capillary retention results in films of intermediate thickness and folded and uneven interfaces (Figure 1b), whose cumulative length is between [L_0, XL_0]. Hence, depending on the magnitude of matric potential, the local configuration of the wetting fluid, and the balance between adsorption and capillary forces, there are three types of wetting films in a typical nonwetting-wetting system (e.g., air-water, oil-water) in porous media: thick film, intermediate film, and thin film (Figures 1a–1c).
Figure 1. The functional relationship between the surface roughness factor X, film thickness factor X_t, interfacial area factor X_a, equivalent film thickness h, and the adsorptive film thickness h_{ad} (in a log-scale axis). The wetting film configurations under different matric potentials are divided into three regimes: (a) thick film, (b) intermediate film, and (c) thin film. Modified from the scheme in Zheng et al., 2015.

Based on the three types of wetting films, a liquid film is assumed to have a normalized equivalent thickness in order to calculate its volume. The equivalent thickness, h, is a function of the matric potential, and represented with a thickness factor X_t, defined as (Zheng et al., 2015):

$$h(\mu) = X_t h_{ad}(\mu) = X_t \sqrt[3]{\frac{A_{svl}}{6\pi\rho\mu}} \qquad (2)$$

where $h_{ad}(\mu)$ is the thickness of the adsorptive film (m) given by the empirical equation above (Iwamatsu & Horii, 1996; Or & Tuller, 1999), μ is the matric potential (J/kg), ρ is the liquid density (998.21 kg/m³ for water), and A_{svl} is the Hamaker constant (J). For air-water-soil systems, the Hamaker constant is usually set at 6×10^{-20} J (Or & Tuller, 1999; Tokunaga, 2011). As discussed by Tuller et al. (1999), this formulation is considered to incorporate the molecular component of disjoining pressure. The terms matric potential μ (J/kg), capillary pressure P_c (Pa), and water pressure head H (cm H₂O) in this study are equivalent. Their unit conversions follow: $\mu = gH$ ($g = 9.81$ m/s²) and $P_c = \rho gH = \rho\mu$ ($\rho = 998.21$ kg/m³ for water). We adopt the same assumption used by Zheng et al., 2015 that the upper limit of the film thickness factor is set equal to the surface roughness factor, i.e., $X_t = X$ at high wetting saturations (thick film). Their simulations and our following work both show that this simplified definition is acceptable for model applications.

The functional relationship between the surface roughness factor X, film thickness factor X_t, interfacial area factor X_a, and the adsorptive film thickness h_{ad} is presented in Figure 1. It is observed that with increasing matric potential, the film thickness factor X_t decreases from X to 1, while X_a increases from 1 to X. At very low wetting saturations (thin film), it is assumed that the wetting phase is retained only by adsorption to the solid surface, i.e., $h = h_{ad}$. In this case, $X_t = 1$ and $X_a = X$. For the special case of smooth solid surfaces, $X = X_t = X_a = 1$. At high wetting saturations, $X_t = X$ and $X_a = 1$. For the intermediate film on a rough surface, we use Zheng et al. (2015)' s exponential equation for the thickness factor:

$$X_t = \begin{cases} X & h_{ad} \geq 10 \text{ nm} \\ X\left(\dfrac{h_{ad}(\mu)}{10}\right)^{\ln X/(\ln 200 - \ln 7)} & 0.35 \text{ nm} < h_{ad} < 10 \text{ nm} \\ 1 & h_{ad} \leq 0.35 \text{ nm} \end{cases} \qquad (3)$$

The adsorptive film thickness $h_{ad}(\mu)$ is a function of only matric potential. The two empirical limits of 10 (wet end) and 0.35 nm (dry end) given in Zheng et al. (2015) correspond to matric potentials $\mu_1 = -3.19$ J/kg (-32.5 cm H₂O) and $\mu_2 = -7.44 \times 10^4$ J/kg (-758400 cm H₂O).
Figure 2. Schematic of the logistic curve for the interfacial area factor (X_a) as a function of adsorptive film thickness (h_{ad}).

The two factors X_a and X_t were considered dependent ($X = X_a X_t$) in Zheng et al. (2015). In contrast, we propose a different approach to quantify X_a, based on the observed relationship between interfacial area and matric potential (Brusseau et al., 2006; Kim et al., 1997; Peng & Brusseau, 2012; Porter et al., 2009). The equation is a generalized logistic curve (Figure 2):

$$X_a = \frac{X + e^{k(h_{ad}-h_m)}}{1 + e^{k(h_{ad}-h_m)}} . \tag{4}$$

The parameters h_m and k are related to the microscale structure of the roughness and its impact on interfacial area. The parameter h_m is the critical adsorptive film thickness that corresponds to an interfacial area factor $(X + 1)/2$, which is close to half of the total surface area roughness factor. The parameter h_m can vary between 0.35 and 10 nm in the intermediate film regime. The parameter k is a "growth rate" factor representing the exponential increase of interfacial area during drainage ($k > 0$). In equations (3) and (4), we use the adsorptive film thickness $h_{ad}(\mu)$ as the argument, instead of matric potential μ, because the values of μ are inconvenient to adjust given $\mu \propto 1/h_{ad}^3$. Upon these definitions, X_a and X_t are independent functions of matric potential for a given porous medium, and both range within [1, X].

2.2. Pore-Scale Model

The BCC method has been used to model soil hydraulic properties for many decades. The BCC approach provides a simple yet effective idealization of pore structure to support the development of conceptual and mathematical models (e.g., Dullien, 1992). Modifications to the standard BCC model have been made to improve the accuracy of simulations, such as employing triangular rather than cylindrical pores (e.g., Helland & Skjœveland, 2006; Tuller et al., 1999). BCC-based models have been used successfully to simulate a variety of phenomenon for many different applications, such as dynamic effects in the capillary-pressure/saturation relationship (Dahle et al., 2005), the flow of water in frozen soil (Watanabe & Flury, 2008), electrokinetic coupling during two-phase flow (Jackson, 2008), and the influence of biofilms on hydraulic properties of soil (Brangari et al., 2017).

We apply the triangular-pore BCC method with the roughness modifications presented in section 2.1 to determine total fluid-fluid interfacial area in one pore. The cross-section of each pore is treated as an equilateral triangle with a side length of L (Figure 3), and the whole porous medium is approximated as a bundle of triangular tubes, similar to previous studies such as Helland and Skjaeveland (2007) and Diamantopoulos and Durner (2013).

The present study is focused on simulating fluid behavior in the main drainage process. Drainage in a triangular pore for a nonwetting/wetting system (typically air/water or oil/water) is assumed to follow a centrally symmetric advance/retreat mechanism (Blunt, 2001; Celia et al., 1995; Diamantopoulos & Durner, 2013; Helland & Skjaeveland, 2007). During the onset of drainage, the invading nonwetting fluid rapidly displaces the wetting fluid from the center of a filled pore, forming a symmetric blob whose dimensions correspond to the pore dimensions. The nonwetting fluid in the center of the pore displaces the wetting fluid to the sides and corners. Hence, the wetting fluid is present as films on each side and as capillary menisci at each corner (Figure 3). The central blob grows as matric potential increases, displacing the menisci further toward each corner and increasing the lengths of the films (Figure 4). Under complete drainage, corner wetting fluid is fully displaced and only wetting film remains.

The geometrical relationships within a partially drained triangular pore are depicted in Figure 3. Assuming a contact angle (θ) of zero, the meniscus wetting fluid at each corner has a curvature radius of $r(\mu)$ corresponding to the matric potential, which follows the Young-Laplace equation:
Figure 3. Cross-sectional scheme of a partially drained equilateral triangular pore and the distribution of corner and film water.

$$r(\mu) = -\frac{\gamma}{\rho\mu} \tag{5}$$

where μ is the matric potential in unit J/kg and γ is the surface tension of the liquid (for air-water $\gamma = 0.0728$ N/m). The area surrounded by the meniscus and two sides of an angle—the corner water saturation of one angle—can be calculated for any regular n-polygons as $A_c = F_n r^2$ (Or & Tuller, 1999). For equilateral triangles, $F_n = 3\sqrt{3} - \pi$. The length of one meniscus curve, which is $\pi r/2$, is the meniscus-associated interfacial area for one corner.

The entire inner solid surface of a pore is assumed to have the same surface roughness everywhere with a constant surface roughness factor X and two logistic parameters k and h_m, all of which are considered to be inherent properties of a specific porous medium. For each given matric potential and associated h_{ad}, there is a unique set of X_t and X_a derived from equations (3) and (4), respectively. The length of wetting film on one side is determined by the meniscus radius $r(\mu)$ (shown in Figure 3).

Thus, the saturation and interfacial area of wetting film can be determined for one side. The saturation and specific interfacial area of wetting fluid in a single pore is determined as the combination of the wetting fluid in the three sides and three corners (Figure 3).

The saturation of wetting phase (S_{wc} and S_{wf}) and the interfacial area between nonwetting and wetting fluids (A_{nwc} and A_{nwf}) in one pore can be derived using the following equations:

$$S_{wc} = \frac{3F_3 r^2(\mu)}{A_3 L^2}, \tag{6}$$

$$S_{wf} = \frac{3h(\mu)[L - 2r(\mu)\cot(\pi/6)]}{A_3 L^2}, \tag{7}$$

$$A_{nwc} = \frac{3\pi r(\mu)}{2A_3 L^2}, \tag{8}$$

$$A_{nwf} = \frac{3X_a[L - 2r(\mu)\cot(\pi/6)]}{A_3 L^2}, \tag{9}$$

where the subscripts "c" and "f" mean corner wetting fluid and film wetting fluid, respectively. A_n is the pore area coefficient to make $A = A_n L^2$ for a regular n-gon with side length L, which is $\sqrt{3}/4$ for equilateral triangles. F_3 is $3\sqrt{3} - \pi$ as mentioned above.

Figure 4. Wetting and nonwetting fluid distributions in a porous medium undergoing drainage for a lognormal pore size distribution and a given matric potential in a SWC curve.

2.3. Sample-Scale Equations

The equations representing a single pore are upscaled to the sample scale using an assumption of a lognormal distribution of pore sizes (e.g., Diamantopoulos & Durner, 2013; Or & Tuller, 1999). The lognormal distribution is a good approximation for the pore-size distribution of a broad range of porous materials (e.g., Diamantopoulos & Durner, 2015). The probability density function of lognormal distribution for variable pore side length (L) is as follows:

$$f(L) = \frac{1}{L\sigma\sqrt{2\pi}}\exp\left(-\frac{[\ln(L/L_m)]}{2\sigma^2}\right) \tag{10}$$

where L_m is the mean pore side length (m) and σ is the standard deviation of $\ln(L)$.

The relationship between pore size, drainage, and wetting-fluid distribution is shown in Figure 4. Under a specific matric potential, pores can be filled, partially drained, or fully drained depending on their sizes. The critical pore size, i.e., the pore size that corresponds to the onset of drainage, can be determined as follows:

$$L_1 = \frac{\gamma}{\rho\mu}C_3 \tag{11}$$

where C_n is the drainage radius coefficient for any regular n-gons. The value for equilateral triangles is $C_3 = 2\left[\sqrt{3} + \sqrt{\pi/\sqrt{3}}\right]$ (Tuller & Or, 2001). The smallest pore size can be set at a random small number such as 5 nm (Or & Tuller, 1999). The largest pore side length ($L_{\max}$) corresponds to the onset of drainage for the largest pore, which is defined by the air entry matric potential μ_d. The expression for $L_{\max}$ is given in Or and Tuller (1999) and Tuller and Or (2001):

$$L_{\max} = L_1(\mu) + 2h(\mu_d) \tag{12}$$

For sample-scale saturation, the total contributions are from fully filled pores (ducts), corner wetting fluid, and film wetting fluid. The upscaling equations of saturation as a function of matric potential yields

$$S_w = S_{wd}(\mu) + S_{wf}(\mu) + S_{wc}(\mu) \tag{13}$$

$$S_{wd}(\mu) = \int_{L_{\min}}^{L_1(\mu)} f(L)dL \tag{14}$$

$$S_{wc}(\mu) = \int_{L_1(\mu)}^{L_{\max}} \frac{3F_3r^2(\mu)}{A_3L^2}f(L)dL \tag{15}$$

$$S_{wf}(\mu) = \int_{L_1(\mu)}^{L_{\max}} \frac{3h(\mu)[L-2r(\mu)\cot(\pi/6)]}{A_3L^2}f(L)dL \tag{16}$$

For sample-scale fluid-fluid interfacial area, there are only contributions from drained pores, including meniscus and film interfaces. Thus, the equations for total fluid-fluid interfacial areas are as follows:

$$A_{nw} = A_{nwf}(\mu) + A_{nwc}(\mu) \tag{17}$$

$$A_{nwc}(\mu) = \int_{L_1(\mu)}^{L_{\max}} \frac{3\pi r(\mu)}{2A_3L^2}f(L)dL \tag{18}$$

$$A_{nwf}(\mu) = \int_{L_1(\mu)}^{L_{\max}} \frac{3X_a[L-2r(\mu)\cot(\pi/6)]}{A_3L^2}f(L)dL \tag{19}$$

The specific solid surface area (SA) is determined as follows:

$$SA = \int_{L_{\min}}^{L_{\max}} \frac{3XL}{A_3L^2}f(L)dL \tag{20}$$

When $X = 1$, the SA corresponds to a geometric smooth surface area.

Inspection of equation (20) shows that SA is a function of X and pore-size distribution. The total interfacial area in equation (17) attains its maximum value under ultrahigh matric potentials where $X_a \rightarrow X$ and $r(\mu) \rightarrow 0$, and it is assumed to be equal to the specific surface area of the solid. Similar assumptions have been used in previous studies such as Or and Tuller (1999) and Peng and Brusseau (2005).

2.4. Limitations of Model Formulation

The use of the triangular-pore BCC approach brings some inherent limitations to the model. Specifically, the geometric smooth surface area determined with equation (20) will typically be larger than the standard geometric smooth-surface values due to the use of the simplified pore geometry. However, the present work focuses on systems with significant surface roughness and film interfacial areas. Hence, the errors in geometric surface areas associated with the BCC approach will have minimal overall impact on application of the model to most natural porous media.

The simplified fluid distribution of three menisci for each pore (Figure 3) may not be representative for all systems because of pore connectivity and merging of menisci. This effect of pore connectivity is not considered in the BCC model, which may affect calculated meniscus interfacial areas. However, this will have minimal impact on determination of total interfacial areas because the contribution of meniscus interfacial area to total interfacial area is typically very small compared to that of film interfacial area (Brusseau et al., 2006, 2007; Or & Tuller, 1999).

Irreducible wetting-fluid saturation, i.e., residual corner wetting fluid, is not present in the standard BBC model. In developing the model, we have attempted to strike a balance between model effectiveness and the number of input parameters. The focus was placed on parameters that are most critical to characterizing interfacial area behavior. Therefore, in the interest of simplicity, no additional modification is made to incorporate residual wetting saturation. The presence of residual saturation would affect primarily meniscus interfacial area, with minimal impact on film interface.

Diamantopoulos et al. (2016) showed that in a glass-bead medium the transition points between films and menisci might have a contact angle greater than zero, which reduces the actual meniscus radius. Nevertheless, they also showed that the wettability of natural grain surfaces is sufficiently high such that assuming zero contact angle is acceptable for many cases. Thus, the present approach is based on a completely wet surface with $\theta = 0$ for all pores. It is noted that a nonzero contact angle can be incorporated by including the specified value in equation (5).

A logistic function is used to describe X_a, which represents the relationship between interfacial area and matric potential, whereas a simpler exponential function is used for X_t (film thickness factor). While a logistic function could be used for X_t similar to the treatment of X_a, it would add additional parameters. It is also noted that X_t affects the simulation of only film saturation and has no impact on the simulation of interfacial area.

We have limited the present formulation to drainage only to focus on the measured data sets. It is straightforward to include imbibition in the BCC approach. The critical point is to determine the geometry of the pore snap-off for imbibition, which can be changed in the variable C_3 in Equation (11).

3. Applications

3.1. Model Parameterization

The model is implemented by determining values for all of the critical parameters, including the air-entry matric potential μ_d, the surface roughness factor X, the pore-size distribution parameters L_m and σ, and the microscale logistic parameters k and h_m. All of the applications presented herein are specific to air-water systems. The influence of these parameters, especially the surface roughness factor, on both P_c-S_w and A_{nw}-S_w curves is examined through a series of simulations. First, the contributions associated with film, meniscus, and duct (filled pore) to total saturation and interfacial area are examined. Second, a sensitivity analysis is conducted for the critical parameters X, L_m, and σ to illustrate their influence and effective range. Third, tests are conducted with measured P_c-S_w (SWC) and air-water A_{nw}-S_w data for three natural porous media to investigate the ability of the model to simulate measured data.

Measured data for the SWC curve and solid surface area are required to apply the model to a specific porous medium. The first step is to determine the air-entry matric potential (μ_d), which in this case was determined via the traditional Brooks and Corey (1964) analysis of the measured SWC curve. The optimized values for L_m, σ, and X are then obtained in a two-step process. First, a random initial value for X is selected, and L_m and σ are optimized by application of the model to the measured SWC data. The optimized values are then substituted into equation (20), via equation (10), to derive the best value of X (with SA measured as note above). The as-obtained X is then used in place of the initial X value, and L_m and σ are optimized again. This iteration is repeated to obtain final optimized values of X, L_m, and σ. The objective function for this optimization is as follows:

$$\Delta S_w = \sqrt{\frac{\sum\limits_{i=1}^{n}(S_{wm}-S_{ws})^2}{n}}, \tag{21}$$

where S_{wm} is the measured saturation and S_{ws} is the simulated saturation via equation (13). This optimization is performed with the nonlinear optimization toolbox in MATLAB.

The simulation of A_{nw}-S_w curves requires the function between the interfacial area factor X_a and matric potential to be determined. With the "simple-exponential" assumption for X_a proposed by Zheng et al. (2015), $X_a = X/X_t = f(P_c)$, without additional parameters. Conversely, our proposed logistic function for X_a assumes $X_a = f(P_c, k, h_m)$, with two logistic parameters, k and h_m, for the microscale roughness. The values of k and h_m for a porous medium can be optimized on a set of measured A_{nw} vs. P_c data with equations (17)–(19). Since measured data sets are usually reported in the form of A_{nw} vs. S_w, each measured S_w can be substituted in the fitted P_c-S_w curve to derive the corresponding P_c for each measured A_{nw} data point (Brusseau et al., 2006).

The total interfacial area is also calculated using the thermodynamic-based method of Leverett (1941) for comparison with our model. The thermodynamic method is a theoretical approach to estimate total fluid-fluid interfacial areas based on the SWC curve of the porous medium. The interfacial area can be computed as follows:

$$A_{nw}(S_w) = \frac{n}{\gamma}\int_{S_w}^{1}P_c(s)ds \tag{22}$$

where $P_c(s)$ is the capillary pressure vs. saturation function and S_w is one given point on the curve, n is porosity, and γ is surface/interfacial tension.

3.2. Measured Data Sets

The efficacy of the model is tested by comparing simulated A_{nw}-S_w curves with measured data sets of total A_{nw} measured with both gas-phase and aqueous-phase IPTT methods. The combined data sets provide measured A_{nw} values for a full range of water saturation. No prior efforts to our knowledge have simulated measured data sets over this full saturation range, especially for very dry conditions ($S_w < 0.2$). The tests will evaluate if the model is able to reproduce the interfacial area over the full range of saturation, including the exponential increase observed at low saturations.

Measured data sets for three porous media are employed: Accusand 40/50, which is a commercial quartz sand, Vinton soil, a surface soil collected in Pima County, AZ, and a natural sandy material reported by Kim et al. (1997, 1999). Properties of the porous media are presented in Table 1. All three media are considered water wetting. Brusseau and colleagues (unpublished data) measured the specific solid surface area and SWC data for Accusand. The full-range of A_{nw}-S_w data were collected from the gas-phase IPTT measurements reported by Peng and Brusseau (2005), the aqueous-phase IPTT measurements reported in Brusseau et al. (2015), and the mass-balance (MB) surfactant tracer measurements reported in Araujo et al. (2015). For Vinton soil, the specific solid surface area and SWC curve were reported by Peng and Brusseau (2012). Combined data from aqueous-phase and gas-phase IPTT were reported in Costanza-Robinson and Brusseau (2002), Peng and Brusseau (2005), and Brusseau et al. (2007). In addition, another

data set of combined gas-phase and aqueous-phase IPTT measurements along with the specific solid surface area and SWC curves, reported by Kim et al. (1997, 1999), was selected.

The measured specific solid surface areas for Vinton (soil) and the other two materials (sand) differ by more than an order of magnitude, providing favorable conditions for evaluating the effect of surface roughness on interfacial area. It is noted that the largest measured air-water interfacial areas obtained with the gas-phase IPTT method for all three media are consistent with specific solid surface areas measured by the nitrogen-BET method. This consistency provides verification of the accuracy of the gas-phase IPTT data and illustrates the significant impact of surface roughness on interfacial area.

4. Results

4.1. Example Simulations

An example set of simulations of both drainage P_c-S_w and A_{nw}-S_w curves for an air-water system is presented in Figure 5, showing the contributions from film, corner, and duct (filled-pore) water for surface roughness factors $X = 10$ and 1,000. Fully filled pores are the primary contributor to total water saturation, as expected. Film and corner water both contribute a small amount to total saturation, but at $X = 10$, the film-associated saturation is very low. The A_{nw}-S_w curves are similar to the examples presented in Or and Tuller (1999) and Brusseau et al. (2007), in which film-associated interfacial area surpasses the meniscus area by more than one order of magnitude at almost all saturation values. The calculated meniscus (corner) interfacial area in Figure 5b may be overestimated because the BCC model neglects pore connectivity. Nevertheless, it is several orders of magnitude smaller than the film interfacial area for both $X = 10$ and 1,000. The uncertainty in

Figure 5. Example calculations of the contributions from duct (filled pores), film, and corner water to the total saturation and air-water interfacial area, with $X = 10$ and $X = 1,000$ and other parameters fixed. The input parameters are set at $L_m = 90$ μm, $\sigma = 0.5$, $\mu_d = -1$ J/kg, $k = 1$, and $h_m = 2$ nm.

total interfacial area due to pore-connectivity effects on simulated meniscus interface can be calculated from the magnitude of meniscus interfacial area in Figure 5b.

Increasing the roughness factor by 100 results in changes in both the P_c-S_w and A_{nw}-S_w functions. The impact of surface roughness on the P_c-S_w curves is relatively small because of the small volume of film-associated water. Conversely, X has a much greater influence on the A_{nw}-S_w relationship. The total interfacial area ranges from 0.5 to 2 logs greater for $X = 1,000$ compared to $X = 10$. The significant increase in interfacial area is observed only for the film contribution, consistent with the fact that surface roughness only affects the film-associated interfaces.

4.2. Sensitivity Analysis

A sensitivity analysis was conducted following the example simulations in section 4.1 by varying the parameters X, L_m, and σ over broader ranges. All default parameters are the same as used for the simulations in section 4.1 unless otherwise specified. The resulting drainage P_c-S_w and A_{nw}-S_w curves are shown in Figure 6.

The P_c-S_w curves are generally not very sensitive to the roughness factor X, but a rougher solid surface does have a relatively higher capability to retain water, causing the P_c-S_w curve to shift slightly upward. In contrast, the P_c-S_w curves are more sensitive to L_m and σ as would be anticipated. Increasing the mean pore size leads to less filled pores for a given matric potential and decreases the fluid retention of the medium. The standard deviation controls the dry-end and wet-end of the simulated P_c-S_w curves. Increasing σ makes the curve broader and sometimes yields a maximum saturation lower than 1 due to the fixed air-entry potential.

The simulations presented in Figure 6 clearly demonstrate that the presence of solid surface roughness, i.e., $X > 1$, increases the magnitude of film interfacial area compared to the case of a smooth surface ($X = 1$). Larger X values produce larger interfacial areas for a given set of conditions, as a larger X represents a larger specific solid surface area due to greater magnitude of surface roughness. These results are consistent with prior experiment-based studies that have reported larger interfacial areas for media with greater surface roughness (Costanza & Brusseau, 2000; Costanza-Robinson & Brusseau, 2002; Peng & Brusseau, 2005; Brusseau et al., 2008, 2010, 2015; Zhong et al., 2016).

The sensitivity of interfacial area curves to the roughness factor is complicated. Inspection of the linear-scale insert of Figure 6a shows that the A_{nw}-S_w functions for media with smooth surfaces ($X = 1$) are essentially linear over the full saturation range for small to moderate σ. The curve for this condition defines one theoretical limiting case for the A_{nw}-S_w function, establishing the minimum values of A_{nw} for a given porous medium. Note that this case is functionally equivalent to the theoretical case wherein the wetting films are sufficiently thick to produce smooth film interfaces for all S_w.

The special case wherein the surfaces are rough and the thicknesses of the wetting films remain sufficiently thin such that the effect of roughness remains at its maximum for all S_w (i.e., $X_t = 1$ and $X_a = X$) defines the other theoretical limiting case. This case establishes the maximum set of A_{nw} values. An example of this second case is provided in Figure 5b for $X = 10$ with the constraint $X_t = 1$ and $X_a = X$, and other parameters the same as for the original simulation. It is observed that A_{nw} values for this case are larger than for the $X = 1,000$ simulation at $S_w > 0.4$, even though the latter system has an equivalent 100-times greater surface roughness.

The actual A_{nw}-S_w function observed for a given porous medium will typically reside somewhere between the two limiting cases. This is illustrated by the observation that the A_{nw} values produced for the original $X = 10$ simulation are an order of magnitude smaller than those for the theoretical maximum simulation. This is a result of thicker wetting films partially masking the impact of roughness on film interfacial area.

Generally, all A_{nw} curves with $X > 1$ greatly increase at a certain saturation due to the impact of surface roughness causing an exponential increase of film-associated interface. For a given set of conditions, the critical saturation is smaller for smaller X (Figure 6). The impact of surface roughness on A_{nw} is masked to some degree at higher saturations because of the presumed presence of thicker wetting films. This masking effect is greater for smaller X for a given set of conditions. The degree to which surface-roughness impacts are masked, and the resultant shape of the A_{nw}-S_w curve, for a given medium will depend upon its fluid-
Figure 6. Sensitivity analysis of the roughness-modified BCC model for drainage matric potential curves and total interfacial area curves on logarithmic scales. The default parameter values for all cases are $X = 50$, $L_m = 90$ μm, $\sigma = 0.5$, $\mu_d = -1$ J/kg, $k = 1$, and $h_m = 2$ nm unless specified otherwise. Adjusted parameters are (a) surface roughness factor; (b) mean pore side length (with two dashed reference curves for the maximum and minimum inputs, respectively, under the same conditions except with $X = 1$); (c) standard deviation (with the same reference curves as (b) for the maximum and minimum inputs). Each interfacial-area figure has an amplified insert showing the curves on linear scales for $A_{nw} < 2000$ cm^{-1}. The A_{nw} insert in Figure 6a has a further magnification for saturations over 30%, and the errors due to meniscus-interfaces on the $X = 100$ curve are marked.

retention characteristics and the nature of the surface roughness, and how they influence pore-scale wetting-fluid distribution and configuration. More detailed discussions of the roughness factor and natural grain surfaces are given in section 5.

For the analyses of the effect of L_m and σ, two reference simulations with smooth media ($X = 1$) were first performed, and the subsequent simulations for rough media ($X = 50$) were set within the parameter range of the reference simulations. As expected, decreasing L_m increases SA due to smaller grain size (and smaller pore size), which results in larger A_{nw} for the full-range of saturations. These results are consistent with prior experiment- and model-based studies that have reported larger interfacial areas for media with smaller grain diameters (Cary, 1994; Anwar et al., 2000; Costanza & Brusseau, 2000; Costanza-Robinson & Brusseau, 2002; Cho & Annable, 2005; Dobson et al., 2006; Schnaar & Brusseau, 2006; Brusseau et al., 2008, 2009, 2010; Costanza-Robinson et al., 2008; Zhong et al., 2016). The relative impact of surface roughness on A_{nw} is greater for smaller L_m, as illustrated by comparing the two sets of simulations for $X = 1$ and $X = 50$ for $L_m = 10$ vs. 160 µm (Figure 6b). For $L_m = 10$, the difference in A_{nw} for $X = 1$ and $X = 50$ is greater than 0.5 log for $S_w < 0.9$. Conversely, the difference in A_{nw} is very small until much lower S_w for $L_m = 160$. These results reflect the relationship between surface area and grain size, wherein the magnitude of L_m (i.e., pore size) correlates to grain size.

Increasing the pore-size standard deviation for smooth media only slightly increases SA, but it causes the A_{nw}-S_w function to become more nonlinear for larger σ (Figure 6c). For rough media, the influence of σ is similar to that observed for the P_c-S_w curves, where increasing σ simultaneously increases the low-saturation A_{nw} for $S_w < 0.3$ and decreases the medium-to-high-saturation A_{nw} at $S_w > 0.3$. Similar to the L_m simulations, it is observed that the deviation between the A_{nw}-S_w curves for the $X = 1$ and $X = 50$ cases is greater for $\sigma = 1.2$ than for $\sigma = 0.1$ at low saturation. This reflects the greater proportion of smaller pores present with larger pore-size (grain-size) distributions. Inspection of the insert in Figure 6c shows that the magnitudes of the impact of σ are relatively smaller than those of X and L_m.

4.3. Tests With Measured Data

The results for model testing with the three measured data sets are shown in Figure 7. The left column in Figure 7 presents the final fit of the SWC curves. The optimized curves produce good matches to the measured data for high and medium saturations, but do not match the measured data at the lowest saturations. Following the methodology in section 3.1, the results for roughness factor X and pore size parameters L_m and σ of the three media are presented in Table 2. Inspection of Table 2 shows that L_m is smallest for Vinton, intermediate for the Kim sand, and largest for Accusand. This is consistent with the textures of the three media. Diamantopoulos et al. (2016) tested a lognormal triangular-BCC model without surface roughness using the same SWC data reported for Vinton soil in Brusseau et al. (2006), yielding values of $L_m = 90$ µm and $\sigma = 0.9$. Their values are similar to ours.

The model simulations of A_{nw}-S_w incorporating the logistic parameters k and h_m are presented in the right column of Figure 7. It is observed that the model simulations provide good matches to the measured data over the entire saturation range for the Accusand and Vinton media. The values of A_{nw} exhibit enormous increases, upward of 2,500 and 40,000 cm^{-1}, respectively, over the full saturation range. These results demonstrate that the model effectively represents these enormous changes in air-water interfacial area during drainage.

For the Kim et al. data, the simulated curve matches at the lowest saturations but overpredicts measured A_{nw} values at middle to high saturations. These errors exceed the range of menisci uncertainties (~10%), and may reflect in part greater uncertainty in the model representativeness of the simplified triangular pore geometry. It is noted that this medium has the smallest interfacial areas and surface-roughness effects, conditions for which errors in representing the pore structure and smooth surface area would have the most impact. The disparity between simulated and measured values may also be influenced by possible uncertainties in the measured aqueous-phase IPTT data discussed by Kim et al. (1997).

The measured and simulated interfacial areas for Vinton soil are much greater than for the two sands. Vinton soil has a much larger X compared to the other two media (Table 2), consistent with its much larger specific solid surface area as measured by the nitrogen-BET method (Table 1). Hence, these results illustrate
Figure 7. Model simulations of the P_c-S_w and A_{nw}-S_w curves compared to measured data for three natural porous media using the simple-exponential and logistic assumptions for the interfacial area factor X_a. Results produced by the thermodynamic estimation method are also plotted.

that X controls the overall magnitude of total interfacial area. It is further observed that the logistic parameters k and h_m also influence the impact of surface roughness on A_{nw}. They are correlated to the surface-roughness masking phenomenon described in the discussion of Figures 5 and 6. The k term controls the slope of the A_{nw}-S_w curves for the exponential-increase stage, and h_m determines the critical

Table 2
Pore Size Distribution and Surface Roughness-Controlling Parameters of the Selected Soil Samples

Medium	Mean pore side length L_m (μm)	Standard deviation σ	Surface roughness factor X	Growth rate factor k	Critical adsorptive film thickness h_m (nm)
Accusand	212.7	0.303	8.7	3.0	10
Vinton	93.6	0.685	58	1.8	5.2
Kim et al.	171.0	0.164	5.0	2.1	6.3

saturation at which A_{nw} begins to increase exponentially. Inspection of Table 2 shows that k and h_m vary somewhat among the three test materials, most likely reflecting differences in the specific structure of surface roughness. Therefore, a minimum of three controlling parameters (X, k, and h_m) are needed to quantify the surface-fluid interactions on rough surfaces, and all three are intrinsic properties of the porous medium. Among them, X represents the overall magnitude of surface roughness (roughness capacity), whereas k and h_m are parameters representing the microscale structure of surface roughness and its interactions with wetting fluid (and ultimately the resultant impact on interfacial area).

For comparison, Figure 7 also shows the simulations obtained through the simple-exponential equation via $X_a = X/X_t$, where X_t is defined by the exponential equation (3). Both simulated curves are consistent and reasonably match the measured interfacial-area data at medium to high saturations ($S_w > 0.5$) for the sand and Vinton soil. However, the measured exponential increases at low saturations are only accurately characterized by incorporating the two logistic parameters k and h_m. The two simulations are very similar over the majority of the saturation range for the Kim data; however, both simulations deviate from the measured data at higher saturations.

The A_{nw}-S_w results obtained with the thermodynamic method are also shown in Figure 7. It is clear that the thermodynamic method greatly underestimates both measured and simulated data sets at lower saturations. The limitations of the base thermodynamic method have been discussed in prior studies, which noted that the method may oversimplify the energy exchange and solid-fluid interactions in real porous media (e.g., Dobson et al., 2006; Grant & Gerhard, 2007; Leverett, 1941; Schroth et al., 2008). If the thermodynamic estimation is considered to provide a first-order representation of the A_{nw}-S_w function for smooth-surface media, the results suggest that Accusand and Vinton have less roughness masking compared to the Kim sand. These results illustrate that the surface-roughness masking effect is different for different porous media.

4.4. Validity of Model Assumptions

Inspection of Figure 7 shows that the optimized curves do not fully match the measured data at the lowest (<0.2) saturations for the P_c-S_w data, which may indicate limitations associated with model assumptions (e.g., simplified pore geometry and fluid distribution, no residual saturation). However, the determination of model parameters L_m, σ, and X is controlled primarily by the higher-saturation (>0.2) data range. Furthermore, determination of parameters k and h_m are based on application to the A_{nw}-S_w data. Thus, any potential model limitations affecting simulation of the P_c-S_w data do not significantly influence determination of interfacial area. This is supported by the excellent matches obtained between the simulated and measured curves for the A_{nw}-S_w data for Accusand and Vinton.

The model assumptions of simplified pore geometry and fluid distribution and of no residual wetting fluid affect primarily the meniscus interfacial area. As discussed above, film-associated interfacial area dominates total fluid-fluid interfacial area at essentially all saturations. Thus, potential uncertainty in meniscus area will have minimal impact on determination of total interfacial area, the focus of this study.

The P_c-S_w function is not very sensitive to surface roughness and wetting-film status, given the relatively small fluid volumes involved. In addition, as noted above, there can be uncertainty in simulation of this function at lower saturations. Thus, our approach of treating X_a independent from X_t and determining it from the A_{nw}-S_w data appears to be a robust means of characterizing fluid-fluid interfacial area.
Figure 8. Illustration of the masking phenomenon of the surface roughness effect on A_{nw}-S_w curves. The blue and red curves represent two media with different magnitudes of surface roughness, but the same smooth surface area (SA).

5. Discussion

5.1. The Masking of the Surface Roughness Effect

The illustrative results in Figures 5–7 all indicate that surface roughness can have a substantial impact on the magnitude of air-water interfacial area. As discussed above, the impact may be masked to some extent depending upon media properties and fluid conditions. The masking phenomenon is illustrated in linear-scale coordinates in Figure 8. The two limiting cases for the A_{nw}-S_w function are shown as the "maximum roughness" and "smooth surface" curves. The curve for the smooth surface ($X = 1$) is anchored to the smooth solid surface area for $S_w = 0$. Curves for $X > 1$ are anchored to the actual (rough) solid surface area. The dashed curves in Figure 8 demonstrate the maximum roughness effect on the A_{nw}-S_w function for a given medium, where all of the wetting films are thin at all S_w ($X_t = 1$ and $X_a = X$). The surface roughness effect can be obscured if the wetting film is sufficiently thick. The solid curves in Figure 8 represent one possible realization of the actual drainage A_{nw}-S_w function, wherein the impact of surface roughness is masked to some degree compared to the maximum-roughness curves.

The typical A_{nw}-S_w curve is "L"-shaped in linear coordinates, with a flat linear stage at higher saturations and a steep exponential stage at lower saturations. Surface roughness may be considerably masked by thick wetting films in the linear stage, causing the actual A_{nw}-S_w curve to reside closer to the theoretical smooth-surface curve. In the exponential stage, the decreasing wetting-film thickness causes an enormous increase in the magnitude of fluid-fluid interfacial area such that the actual A_{nw}-S_w curve approaches the theoretical maximum curve. The nature of surface roughness and its interaction with wetting fluid determines the relative proportion of linear and exponential stages over the full saturation range. From the simulations of the measured data presented in Figure 7, it can be observed that different materials have different proportions of linear and exponential stages. For instance, the linear range for Kim's sand extends to ~30% saturation, whereas it extends to only ~70–80% for Accusand and Vinton. Such results indicate that the masking of surface roughness is more significant for Kim's sand than for Accusand and Vinton soil.

As noted above, the degree to which surface-roughness impacts are masked and the resultant shape of the A_{nw}-S_w curve for a specific porous medium will depend upon the interplay between wetting-film configuration, matric potential (saturation), and surface roughness. The shape of the A_{nw}-S_w curves can be explained in accordance with the five controlling parameters in the model: L_m, σ, X, k, and h_m. The lognormal pore-size-distribution parameters L_m and σ define the geometric base solid surface area and determine the location of the smooth-surface fluid-fluid interfacial area curve. Combining the surface roughness factor X with the smooth-surface curve defines the maximum-roughness fluid-fluid interfacial area curve for a given medium. These two limiting curves determine the full range of possible outcomes of surface roughness effects on fluid-fluid interfacial area for a specific medium. The parameters k and h_m, which represent the microstructure of solid surfaces and its interaction with wetting fluid, influence the shape of the curve within the limiting range and the proportion of the linear and exponential stages. For media with rough solid surfaces, the A_{nw}-S_w curve will always reside between the smooth-surface curve and the maximum-roughness curve, and the magnitudes of the three roughness-related parameters (X, k, and h_m) will mediate the overall impacts of surface roughness on A_{nw} under different matric potentials (wetting saturations) and thus the overall shape of the A_{nw}-S_w curve.

The following strategies can be implemented to improve the characterization of surface roughness effects on nonwetting-wetting interfaces. First, the extent of drainage can be increased to reach as low a saturation as possible. This will entail the use of additional measurement methods beyond the standard ones typically used to determine soil-water characteristic curves (e.g., Arthur et al., 2013). Second, whereas most studies focus on a single medium or on a few ideal media, it is better to use various porous media with a broad range of physical properties. One major implication of this work is that natural soils and sediments are anticipated
Figure 9. Scheme of a rough solid surface with multiple layers of roughness. The root-mean-square roughness defines the roughness of the primary layer. When matric potential increases, the water film thickness may reduce to the scale of the secondary or further microroughness levels, which provides additional surface and interfacial areas.

to exhibit a great range of properties and associated A_{nw}-S_w behavior. Thus, we would expect that the importance of film-associated interfacial area and the impacts of surface roughness will vary from media to media. Third, use a definition of surface roughness that compares the rough and geometric solid surface areas under different scales, rather than only a single absolute value of specific surface area or relative height (root-mean-square roughness).

5.2. Relating Surface Roughness Effect to Solid Surface Microstructure

The impact of surface roughness on the A_{nw}-S_w function can be explained using concepts of fractal geometry. In the scheme of a fractal surface (Figure 9), there are multiple layers of roughness structures within a defined space. The primary roughness layer, as indicated by the root-mean-square roughness (R_{rms}), is quantifiable by traditional measurements. For natural materials, its spatial scale is usually in the range of 0.1–1 μm or even larger (e.g., Adams et al., 2012; Alshibli & Alsaleh, 2004; Araújo & Brusseau, 2019; Kibbey, 2013; Kim et al., 2012; Tokunaga et al., 2003). At higher water saturations, the film thickness can be close to the magnitude of the primary roughness layer (Kibbey, 2013; Kim et al., 2012; Philip, 1978; Zheng et al., 2015). Under this condition the smaller-scale roughness does not impact film interfacial area. Conversely, adsorbed wetting-film thickness under low-saturation conditions can be 1–10 nm (Resurreccion et al., 2011; Tokunaga, 2011; Tokunaga et al., 2003), which can be several orders of magnitude smaller than the scale of the primary roughness. When the wetting film thickness is reduced to the scale of a certain roughness layer, as shown in the inset of Figure 9, it reflects the microscale surface topography. The transition between scales causes the film interfacial area to increase dramatically, resulting in the exponential stage of the A_{nw}-S_w function. When S_w approaches zero, the film attains the fractal dimensions of the solid surface, where the thickness factor $X_t = 1$ and the interfacial area factor $X_a = X$. These sublevels of roughness are regarded as "microscale roughness" in the present study in distinction to traditional root-mean-square surface roughness (R_{rms}).

The role of the surface roughness factor X can be further interpreted in accordance with the fractal nature of the solid surface. In this case, X can be viewed to represent the potential of surface fractal growth, i.e., the potential for existence of additional scales of roughness that will typically be operationally defined by specific measurement methods (such as nitrogen-BET). The logistic parameters k and h_m reflect the impact of solid fractal structures on the disposition of liquid films. The exponential growth-rate parameter k may indicate the fractal complexity of the surface roughness, especially the difference of average heights between two adjacent roughness layers. The critical adsorptive film thickness h_m—corresponding to a specific matric potential—may represent the average microscale triggering point of the exponential increase of film interfaces. The parameters k and h_m relate to the masking of surface roughness by wetting films, and can be used to quantify the degree of masking. The impacts of the three parameters X, k, and h_m are superimposed on the absolute magnitude of solid surface available, which is controlled by the texture of the porous medium (mean grain size, grain-size distribution).

6. Conclusions

A triangular-pore BCC-based model with explicit representation of surface roughness was developed to characterize the impacts of surface roughness on fluid-fluid interfaces in porous media. The model can compute both the film and meniscus A_{nw}-S_w profiles for a specified porous medium under the assumption of a lognormal pore-size distribution. The model contains three roughness-related parameters: the solid surface roughness factor X, and the microscale film-interface parameters k and h_m, which are all considered to be inherent properties of the porous medium.

The results demonstrated that the model is able to reproduce measured air-water interfacial area data across a full-saturation range, which was not examined in previous modeling studies. The simulations also showed that the exponential increases in A_{nw} measured with the gas-phase IPTT method can be explained by the

impact of surface roughness on film-associated interfacial area. While the applications presented herein were specific to air-water systems, the model and reported outcomes are relevant for any nonwetting-wetting fluid pair. The significance of solid surface properties in mediating fluid-fluid interfacial area observed in this study is consistent with prior research illustrating the role of surface properties on vapor adsorption, water evaporation, and soil-water retention at very high matric potentials (e.g., Leão & Tuller, 2014; Shahraeeni & Or, 2012; Song & Boily, 2013).

The degree to which fluid-fluid interfacial area is influenced by roughness is a function of fluid-retention characteristics and the nature of the rough surfaces, which mediate the distribution and configuration of wetting fluid within the pores and on the surfaces of the solids. The A_{nw}-S_w function observed for a particular porous medium ranges between an upper theoretical maximum, defined for the case wherein the wetting films remain thin for all S_w, and the lower theoretical minimum defined for the case of smooth solid surfaces (and equivalently wherein wetting films remain sufficiently thick for all S_w). The specific behavior is defined with the five controlling parameters in the model: L_m, σ, X, k, and h_m.

The lognormal pore-size-distribution parameters L_m and σ define the geometric base solid surface area and determine the location of the smooth-surface fluid-fluid interfacial area curve. The surface roughness factor X superimposed on the smooth-surface curve determines the maximum-roughness curve for a given medium. These two limiting curves define the full range of possible outcomes of surface roughness effects on fluid-fluid interfacial area for a specific medium. The parameters k and h_m, which represent the microstructure of solid surfaces and its interaction with wetting fluid, mediate the shape of the curve within the limiting range and the proportion of the linear and exponential stages. The influence of wettability, solution chemistry, and other factors is implicitly incorporated in the model through these parameters. Sensitivity analyses were conducted for L_m, σ, and X to examine their influence on system behavior. Because of their hypothesized relationship to the specific nature of surface roughness, we have reserved detailed analysis of k and h_m to a future study wherein the model will be applied to a larger number of porous media beyond the three used in the present study.

The impact of surface roughness on fluid-fluid interfacial area for natural porous media is likely to be masked to some degree due to the presence of wetting films. The extent to which this masking phenomenon occurs will depend on the specific properties of the medium as well as fluid conditions, as illustrated by the results presented herein for the simulation of the measured data sets. It is anticipated that natural porous media will display a wide range of masking potentials considering the extreme variability in physical and geochemical properties exhibited across the spectrum of soils and sediments.

The triangular-pore BCC approach used in this work has limitations that may impose constraints to the representativeness for some systems. This may lead to uncertainties in the magnitudes of simulated meniscus interfaces, the geometric solid surface area, and the fitting of SWC curves at low saturations. However, these potential uncertainties do not limit the capability of the model to characterize the impact of surface roughness on fluid-fluid interfacial area, as shown by application to the measured data sets presented herein. Some of the assumptions used in the present study can be relaxed, for example by implementing consideration of pore-connectivity or effects of nonzero contact angles. In addition, the model can be extended to characterize the imbibition A_{nw} curves by modifying the pore geometry for the onset of pore snap-off.

The modeling approach presented can be used to characterize a broad range of porous media with different solid surface structures. In principle, the A_{nw}-S_w function can be viewed as a "surface-film characteristic curve," containing information about the properties of surface roughness and solid (surface)-fluid (film) interactions. The surface-film characteristic curve can serve as a quantitative approach to characterize rough surfaces, and simulate the associated wetting films in pore-space modeling. This approach is anticipated to provide additional insight into surface roughness effects on porous-media systems.
